Preface

During the fall quarter of 1981, I took a basic course in low-speed aerodynamics, AE 5.35 Aerodynamics. Major Eric J. Jumper was the instructor for the course. While covering thin-airfoil theory, he suggested a possible thesis project to verify theoretical predictions concerning the flapped airfoil by collecting experimental data in the 5 Foot Wind Tunnel. I became interested and decided to tackle the project because it combined theory with experiment. This thesis is the end result of that decision.

I would like to thank my thesis advisor, Major Jumper, for his guidance and assistance throughout the project; Professor Harold C. Larsen for sharing some of his vast knowledge and experience with me; Mr. Jack Tiffany and Mr. Russell Murray for their model construction and timely responses to modifications; and Mr. Wales S. Whitt and Mr. Nicholas Yardich for their tunnel operation. Special thanks to my wife, Linda, who is now a bona fide number cruncher and frustrated typist.

Abstract

This investigation compared thin-airfoil theory predictions of change in zero-lift angle of a tack divided by flap deflection ($\Delta\alpha_{L0}/\eta$) versus flap-hinge location (E) and change in moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/\eta$) versus E to wind tunnel studies of the same effect for a cambered airfoil. This comparison for cambered airfoils has not been previously reported. The NACA 4412 airfoil was chosen for this study. Results of this study show that thin-airfoil theory does predict the trend of the data. The $\Delta\alpha_{L0}/\eta$ versus E prediction favorably matched the data. The $\Delta C_{mac}/\eta$ versus E data differed from the predictions in a similar way to that reported for uncambered airfoils; however, the data in this investigation showed less favorable agreement to thin-airfoil theory than the previously reported results. This difference might be explained in part by the experimental setup used in this study.

WIND TUNNEL INVESTIGATION
OF VARYING HINGED FLAPS

I Introduction

Objective

The objective of this thesis was to compare thin-airfoil theoretical predictions of the change in zero-lift angle of attack divided by flap deflection ($\Delta\alpha_{LO}/\eta$) versus flap-hinge location (E) and the change in moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/\eta$) versus E to wind-tunnel studies of the same effects for the moderately cambered NACA 4412 airfoil.

Background

In thin-airfoil theory, the airfoil is replaced with its mean camber line. Point vortices with a differential strength of γdx are then distributed continuously along the mean camber line to induce velocities which, when added vectorially to the free-stream velocity, produce velocities tangential to the mean camber line. Because the maximum camber is usually small in comparison to the chord, the boundary conditions for the flow can be satisfied on the chord instead of at the mean camber line. This produces an induced velocity (V_{in}) at x_0 such that

$$V_{in}(x_0) = \frac{1}{2\pi} \int_0^C \frac{\gamma(x)dx}{x - x_0} \quad (1)$$

at each point on the chord line. With the assumption of small angles, the free-stream velocity's normal component to the mean camber line ($V_{\infty n}$) is such that

$$V_{\infty n} = V_{\infty} \left[\alpha - \frac{dz}{dx} \right] \quad (2)$$

The induced velocity must also be equal to the negative of $V_{\infty n}$ at x_0 if there is to be no flow through the airfoil, i.e.

$V_{in} = -V_{\infty n}$. So, from equations 1 and 2

$$\frac{1}{2\pi} \int_0^c \frac{\gamma(x) dx}{x - x_0} = V_{\infty} \left[\frac{dz}{dx}(x_0) - \alpha \right] \quad (3)$$

By specifying a $\gamma(x)$ -distribution, the shape of the mean camber line and α to produce such a distribution can be found or vice versa. The only restriction on the $\gamma(x)$ -distribution is the Kutta condition, $\gamma(c) = 0$, which must be applied to determine the circulation and keep $V_{in}(c)$ finite so that the flow can leave smoothly and tangentially from the trailing edge as in a real viscous flow.

By using the transformation $x = \frac{c}{2}(1 - \cos \theta)$, the relationship $[\cos(n-1)\theta - \cos(n+1)\theta]/2 = \sin n\theta \sin \theta$, the definite integral $\int_0^{\pi} \frac{\cos n\theta}{\cos \theta - \cos \theta_0} d\theta = \pi \left[\frac{\sin n\theta_0}{\sin \theta_0} \right]$, and expanding γ into a fourier series of the form

$$\gamma = 2V_{\infty} \left[A_0 \frac{(1 + \cos \theta)}{\sin \theta} + \sum_{n=1}^{\infty} A_n \sin n\theta \right] \quad (4)$$

the induced velocity or left hand side of equation 3 now becomes

$$V_{in}(\theta) = V_{\infty} \left[-A_0 + \sum_{n=1}^{\infty} A_n \cos n\theta \right] \quad (5)$$

Equations 3 and 5 imply that

$$\frac{dz}{dx} = (\alpha - A_0) + \sum_{n=1}^{\infty} A_n \cos n\theta \quad (6)$$

Equation 6 has the form of the cosine series expansion of $\frac{dz}{dx}$. For a given mean camber line $\frac{dz}{dx}$ is a known function of θ , and therefore the values of A_0 and A_n may be written directly as

$$A_0 = \alpha - \frac{1}{\pi} \int_0^{\pi} \frac{dz}{dx} d\theta \quad (7)$$

and

$$A_n = \frac{2}{\pi} \int_0^{\pi} \frac{dz}{dx} \cos n\theta d\theta \quad (8)$$

Since the section lift(ℓ) equals the density times the free-stream velocity times the circulation ($\rho V_\infty \Gamma$) where Γ equals the integral of differential γ distribution over the chord $\left[\int_0^c \gamma dx \right]$, the aerodynamic coefficient, C_ℓ , defined as $\ell / \frac{1}{2} \rho V_\infty^2 c$, can now be rewritten as

$$C_\ell = \frac{2}{V_\infty c} \int_0^c \gamma dx \quad (9)$$

By using equation 4 for γ , and carrying out the integral in equation 9, C_ℓ can be found in terms of A_0 and A_1 as

$$C_\ell = 2\pi A_0 + \pi A_1 \quad (10)$$

Replacing A_0 and A_1 with their integral forms from equations 7 and 8

$$C_\ell = 2\pi \left[\alpha + \frac{1}{\pi} \int_0^{\pi} \frac{dz}{dx} (\cos \theta - 1) d\theta \right] \quad (11)$$

The angle of attack which makes the lift or the lift coefficient in equation 11 equal to zero is called the angle of zero lift, α_{L0} . Applying the definition of α_{L0} to equation 11 gives

$$\alpha_{L0} = \frac{-1}{\pi} \int_0^{\pi} \frac{dz}{dx} (\cos \theta - 1) d\theta \quad (12)$$

A similar development for C_{mac} will give

$$C_{mac} = \frac{1}{2} \int_0^{\pi} \frac{dz}{dx} (\cos 2\theta - \cos \theta) d\theta \quad (13)$$

(Refs 1:44-47 and 2:116-132)

Equations 12 and 13 are used in Section II to predict influences from varying sizes of simple hinged flaps.

II Numerical Solution for Thin-Airfoil

Cambered Airfoils

As we saw in Section I, thin-airfoil theory produces integral equations for C_{mac} and α_{LO} . By assuming that the camber line is made up of straight line segments, these equations can be rewritten as follows (Ref 3:34)

$$\alpha_{LO} = \frac{-1}{\pi} \int_0^{\pi} \frac{dz}{dx} (\cos \theta - 1) d\theta = \frac{-1}{\pi} \sum_{i=1}^n \left[\frac{dz}{dx} \right]_i \int_{\theta_i}^{\theta_{i+1}} (\cos \theta - 1) d\theta \quad (14)$$

and

$$C_{mac} = \frac{1}{2} \int_0^{\pi} \frac{dz}{dx} (\cos 2\theta - \cos \theta) d\theta = \frac{1}{2} \sum_{i=1}^n \left[\frac{dz}{dx} \right]_i \int_{\theta_i}^{\theta_{i+1}} (\cos 2\theta - \cos \theta) d\theta \quad (15)$$

or, after evaluating the straight line segment integrals

$$\alpha_{LO} = \frac{-1}{\pi} \sum_{i=1}^n \left[\left[\frac{dz}{dx} \right]_i \left[(\sin \theta_{i+1} - \theta_{i+1}) - (\sin \theta_i - \theta_i) \right] \right] \quad (16)$$

and

$$C_{mac} = \frac{1}{2} \sum_{i=1}^n \left[\left[\frac{dz}{dx} \right]_i \left[\left[\frac{\sin 2\theta_{i+1} - \sin \theta_{i+1}}{2} \right] - \left[\frac{\sin 2\theta_i - \sin \theta_i}{2} \right] \right] \right] \quad (17)$$

These equations can be numerically integrated through the summation sign by using a digital computer as long as $\frac{dz}{dx}$, θ_i , and θ_{i+1} can be determined for each straight line segment.

The correctness and accuracy of the above equations can be checked by evaluating α_{LO} and C_{mac} analytically and then numerically with the computer for the same airfoil. Since this investigation used the NACA 4412 airfoil which has its

camber line in functional form, both methods can be accomplished for the zero flap deflection case. The analytic solutions as given in Appendix A yield $\alpha_{L0} = -4.1544826^\circ$ and $C_{mac} = -.1062391$. The numerical computer solution using 400 straight line segments yields $\alpha_{L0} = -4.1540554^\circ$ and $C_{mac} = -.1062276$. While the computer solution is a crude, brute force method, it gives extremely accurate results. Appendix B contains the program from which α_{L0} and C_{mac} for the 4412 were computed.

Flapped Airfoils

The influence of small flap deflections on α_{L0} and C_{mac} can also be found through computer numerical integration. Figure 1a shows the coordinate system arrangement for an arbitrarily cambered thin airfoil at an arbitrary angle of attack under which the α_{L0} and C_{mac} numerical equations hold. By choosing any point along the cambered line as a hinge point for a flap deflected by an amount n , the thin airfoil in Fig. 1a changes to that in Fig. 1b. α_{L0} and C_{mac} may be computed for the flap deflected airfoil by defining a new coordinate system (z' and x') as shown in Fig. 1c. Before the α_{L0} and C_{mac} s of the flapped and unflapped airfoils can be compared to arrive at $\Delta\alpha_{L0}/n$ and $\Delta C_{mac}/n$ for particular flap-chord ratios, corrections, if they exist, for using the z' and x' coordinates as the computational axes must be applied to the new α_{L0} and C_{mac} . Because α_{L0} is an angle dependent upon the coordinate system for its value, the angle ($\alpha' - \alpha$) between the coordinate systems in Fig. 1c must be subtracted from the new or flapped airfoil α_{L0} . No correction is necessary for

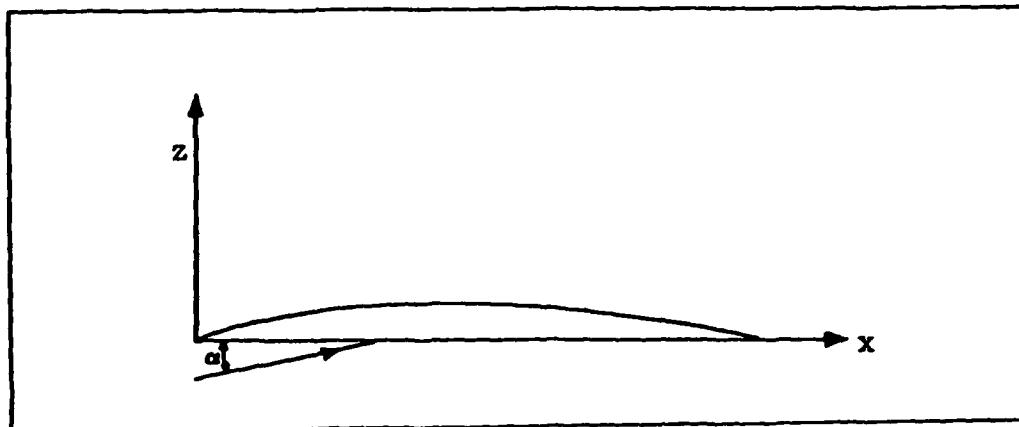

Fig. 1a Coordinate system for an arbitrary airfoil and angle of attack.

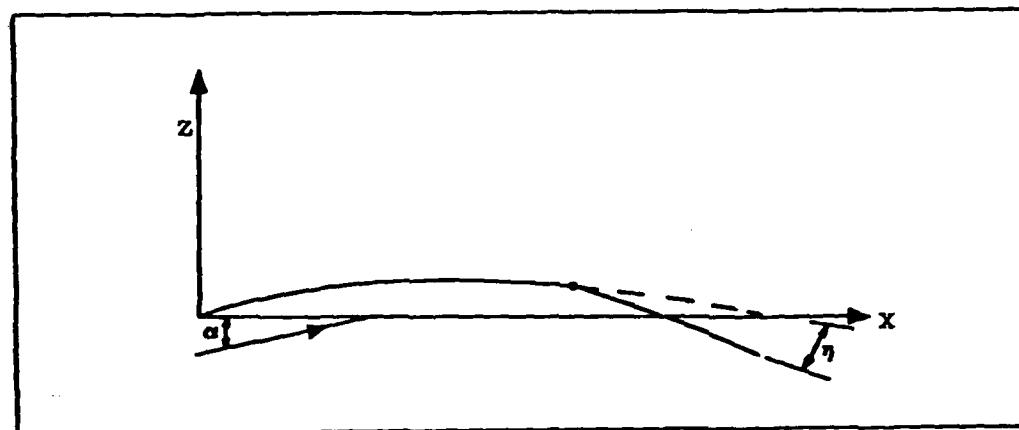

Fig. 1b Flap arbitrarily chosen and deflected.

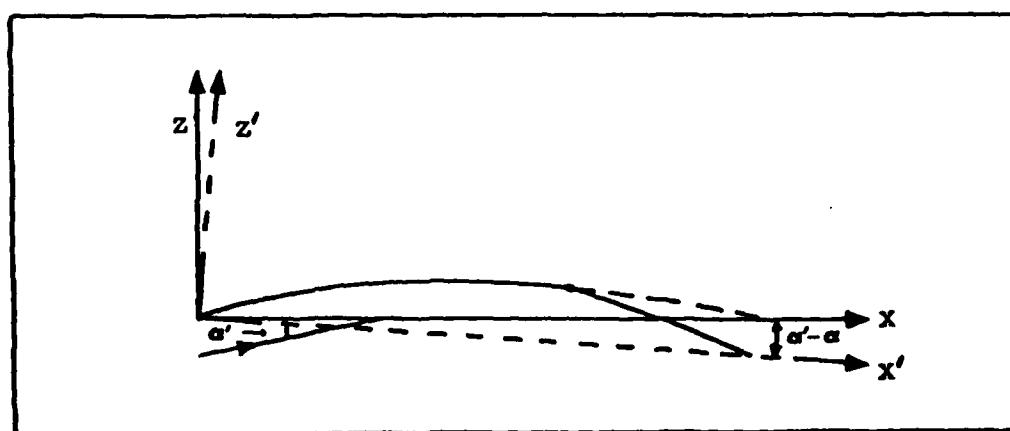

Fig. 1c New coordinate system (x' , z') to find new α_{L0} and C_{mac} .

the new C_{mac} since it is related to the airfoil and not the coordinate system. By doing this for many points along the camber line of an NACA 4412 airfoil one can obtain the curves in Figs. 2 and 3 depicting the influence of small flap deflections on α_{L0} and C_{mac} . Reference Appendix B for the program used to find the data points for Figs. 2 and 3.

Figures 2 and 3 show flap influences for a 4% cambered airfoil. If the camber is different, then slightly different curves will result for $\Delta C_{mac}/\eta$ versus E with the differences for $\Delta \alpha_{L0}/\eta$ versus E due to camber being negligible. This effect of camber on the $\Delta C_{mac}/\eta$ can be shown by comparing 4%, 2%, and uncambered airfoils as in Fig. 4. In general, even the largest difference among the cambered airfoils and uncambered airfoil is small. The above results can be checked by comparing them to predictions which have not been derived in a numerical manner. Chow's (Ref 2:133-137) analytic derivation of $\Delta \alpha_{L0}/\eta$ versus E and $\Delta C_{mac}/\eta$ versus E for uncambered airfoils results in exactly the same curves derived through numerical integration for uncambered airfoils, as they should be in order for the numerical integration approach to be valid. Chow goes on to state that because all angles are small, it is sufficient to find the properties of an uncambered airfoil at zero angle of attack with flap deflected and add them directly to the properties of the cambered airfoil at any angle of attack. That statement agrees with the small differences noted between the uncambered and cambered airfoils for $\Delta C_{mac}/\eta$ versus E and also serves to validate the numerical approach as explained here.

III Wind Tunnel Investigation

Models

The models for wind tunnel testing were constructed by the AFIT Model Fabrication Division. The basic components of a test model are shown in Fig. 5. Components common to all models were the flap deflection mechanism, the side plates, and the rear lift bar. The airfoil component consisted of two sections that varied because of changes in the flap-hinge location. The change in flap-hinge location thereby produced seven different models with flap-hinge locations at 20%, 30%, 40%, 50%, 60%, 70%, and 80% of chord, or expressed in flap-chord ratio, .2, .3, .4, .5, .6, .7, and .8, respectively.

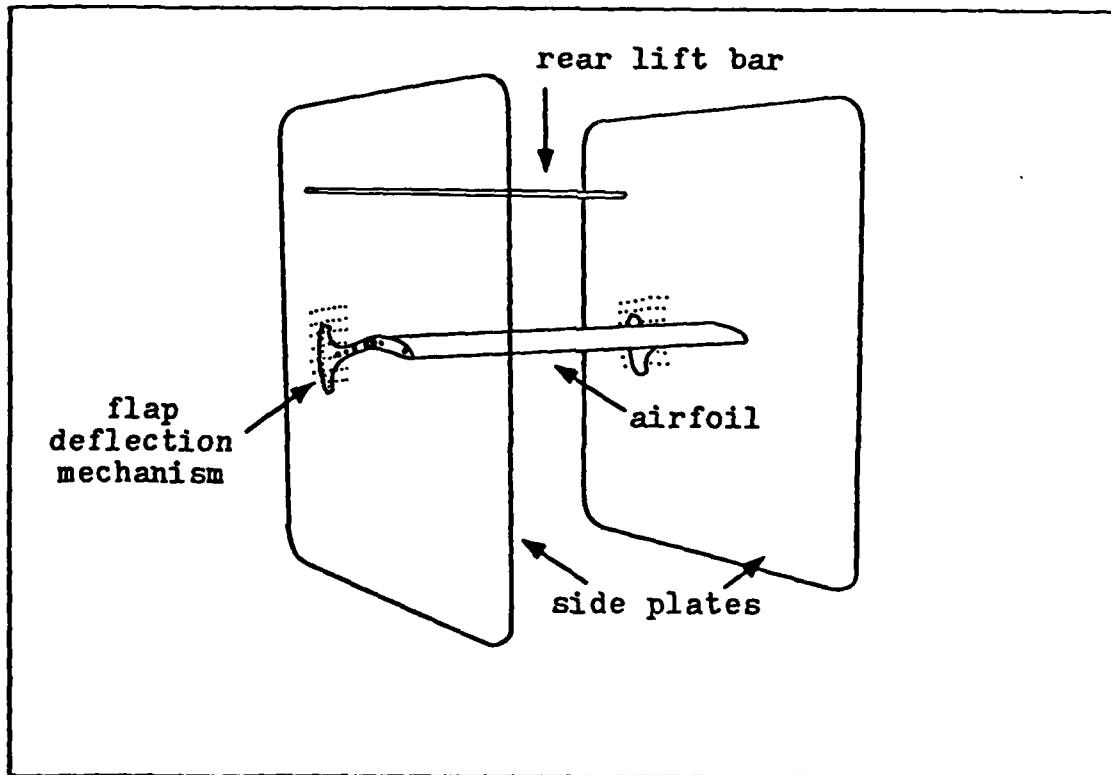

Fig. 5 Basic components of a fully assembled model

The flap deflection mechanism consisted of two identical brass plate. see Fig. 6. Holes B through G served to attach the brass plates to only the flap section of the airfoil being tested. Hole A of the brass plates allowed headed screws to be freely inserted, through both the side and brass plates, into tressed holes in the airfoil flap section. This established an axis of rotation about which the flap section was moved. Holes 1 through 7 of the brass plates made it possible to set the flap at prescribed angles of deflection when used in conjunction with corresponding holes in the side plates. Appendix D gives a detailed explanation of how the brass plates were used to establish a desired flap setting.

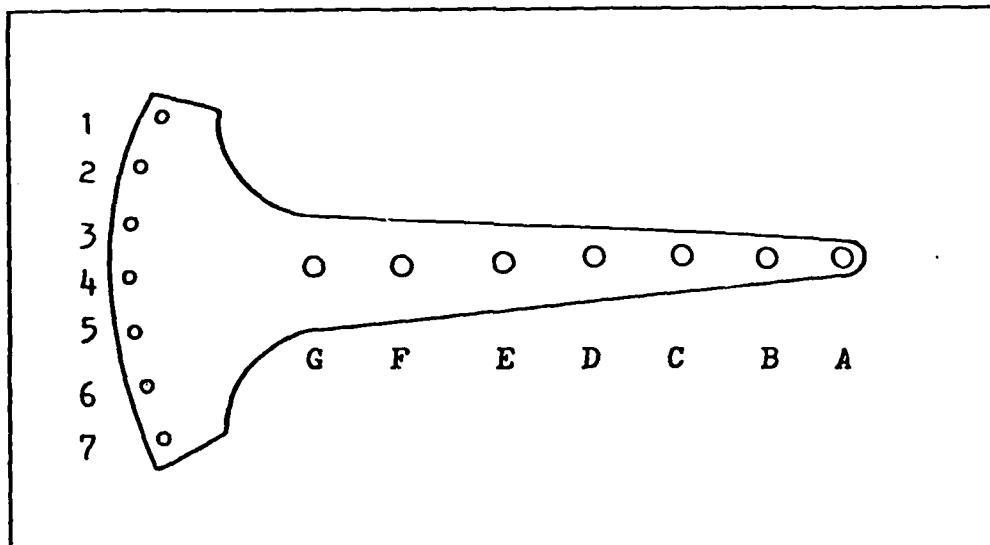

Fig. Brass flap deflection plate with flap attachment holes (B-G), flap deflection holes (1-7), and flap-hinge hole (A).

The two side plates brought all the components together to form a fully assembled model ready for testing. The side plates were constructed of 3/8-inch clear plexiglass with beveled edges and rounded corners. These plates served three

additional functions. First, they served as end plates to simulate two-dimensional flow. Secondly, they captured the airflow far enough upstream of the airfoil's influence so that the tunnel's free stream value for the dynamic pressure could be used in the two dimensional analysis. Finally, the light weight and transparency of the plexiglass side plates facilitated the change from one model to another and allowed viewing of the model during testing.

The rear lift bar was constructed from tubular aluminum with the cross section shown in Fig. 7. This bar was connected to the rear lift wire of the wind tunnel. The bar design for rear lift wire attachment eliminated possible interference problems between the deflecting flap and the rear wire attachment mechanism. It did minimize the number of model measurements needed to set angles of attack and/or flap deflections. It also kept tunnel calibrations to a minimum since only one in-tunnel calibration of a model was required to be able to set any angle of attack and flap deflection combination. Additionally, it eliminated any construction or structural problems associated with having the rear lift attachment mechanism as part of the airfoil. While the bar eliminated many possible problems and minimized many operational problems, it was not wholly satisfactory. The shape of the bar as shown in Fig. 7 led to data errors which had to be accounted for as discussed in Section IV.

The seven NACA 4412 airfoils used for the investigation were made of solid aluminum based epoxy resin. Each airfoil consisted of two matched but separate sections; a front

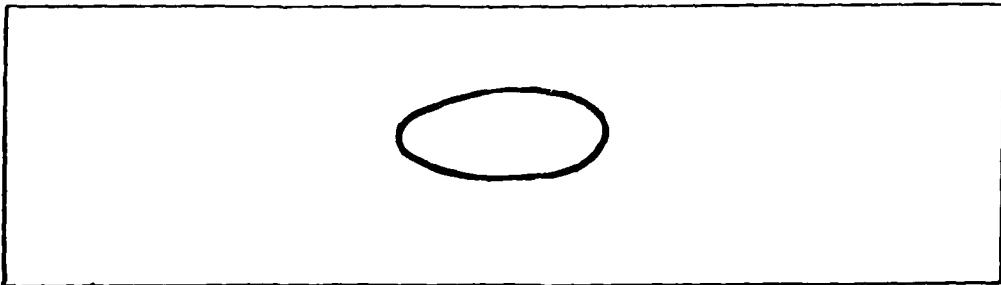

Fig. 7 Cross section of lift bar drawn to actual size.

section that remained fixed, and a flap section which rotated relative to the side plates and the front section. Figure 8 shows the seven airfoils and the difference in size of the flap section among airfoils. Each front section had two attachment fittings in the leading edge for the drag and front lift wires. The matched airfoil sections, which formed 4412s when put together at zero flap deflection, were made from different one piece 4412s because of the chord distance and front section surface lost when a flap section was cut and shaped. Thus, a flap section of $E = .6$ was matched with an appropriately shaped front section that resulted from producing a flap section with at least a flap-chord ratio of .1 less than .6. The one piece 4412s came from a mold made from a wooden 4412 airfoil of two foot span and nine inch chord. The mold insured that each model was the same for all practical purposes. The similarity of models was checked through model measurement prior to testing. It was confirmed by the excellent agreement between models for α_{L0} and the slope of the C_L versus α curve.

See Appendix C for detailed model geometry and measurements.

Fig. 8 Investigation airfoils showing the different sizes of the flap section. From top to bottom, left to right: $E = .8, .7, .6, .5, .3, .2$, and $.4$.

Wind Tunnel

The AFIT Five-Foot Wind Tunnel was used for the wind tunnel investigation. It is an open return, closed test section wind tunnel with a 5 ft circular cross section as shown in Fig. 9. The two counter rotating 12 ft fans of the wind tunnel are powered by four 400-horsepower direct current motors easily capable of producing the tunnel's top empty speed of 350 mph. The speed limit prevents further cracking of the fan blades at high power settings. The aerodynamic forces on the models were determined by using the wind tunnel's wire balance measuring system consisting of three springless scales connected to the model through separate wire systems. The wind tunnel's wire balance system was checked and aligned prior to beginning the runs for each model.

Installation

Prior to installation in the wind tunnel, the holes in the side plates were covered with tape on the sides facing the tunnel wall to prevent 3-D effects and the gaps between the front airfoil section and the flap section were sealed with modeling clay. Each model was then carefully measured on a surface plate using an inclinometer and a height gage. The measurements were used to determine the angle of balance for the wire system. The angle of balance then determined the distances necessary for setting angles of attack for the model. Appendix C contains a more detailed explanation of the model geometry and calculations involved.

The model was then installed in the test section. Instal-

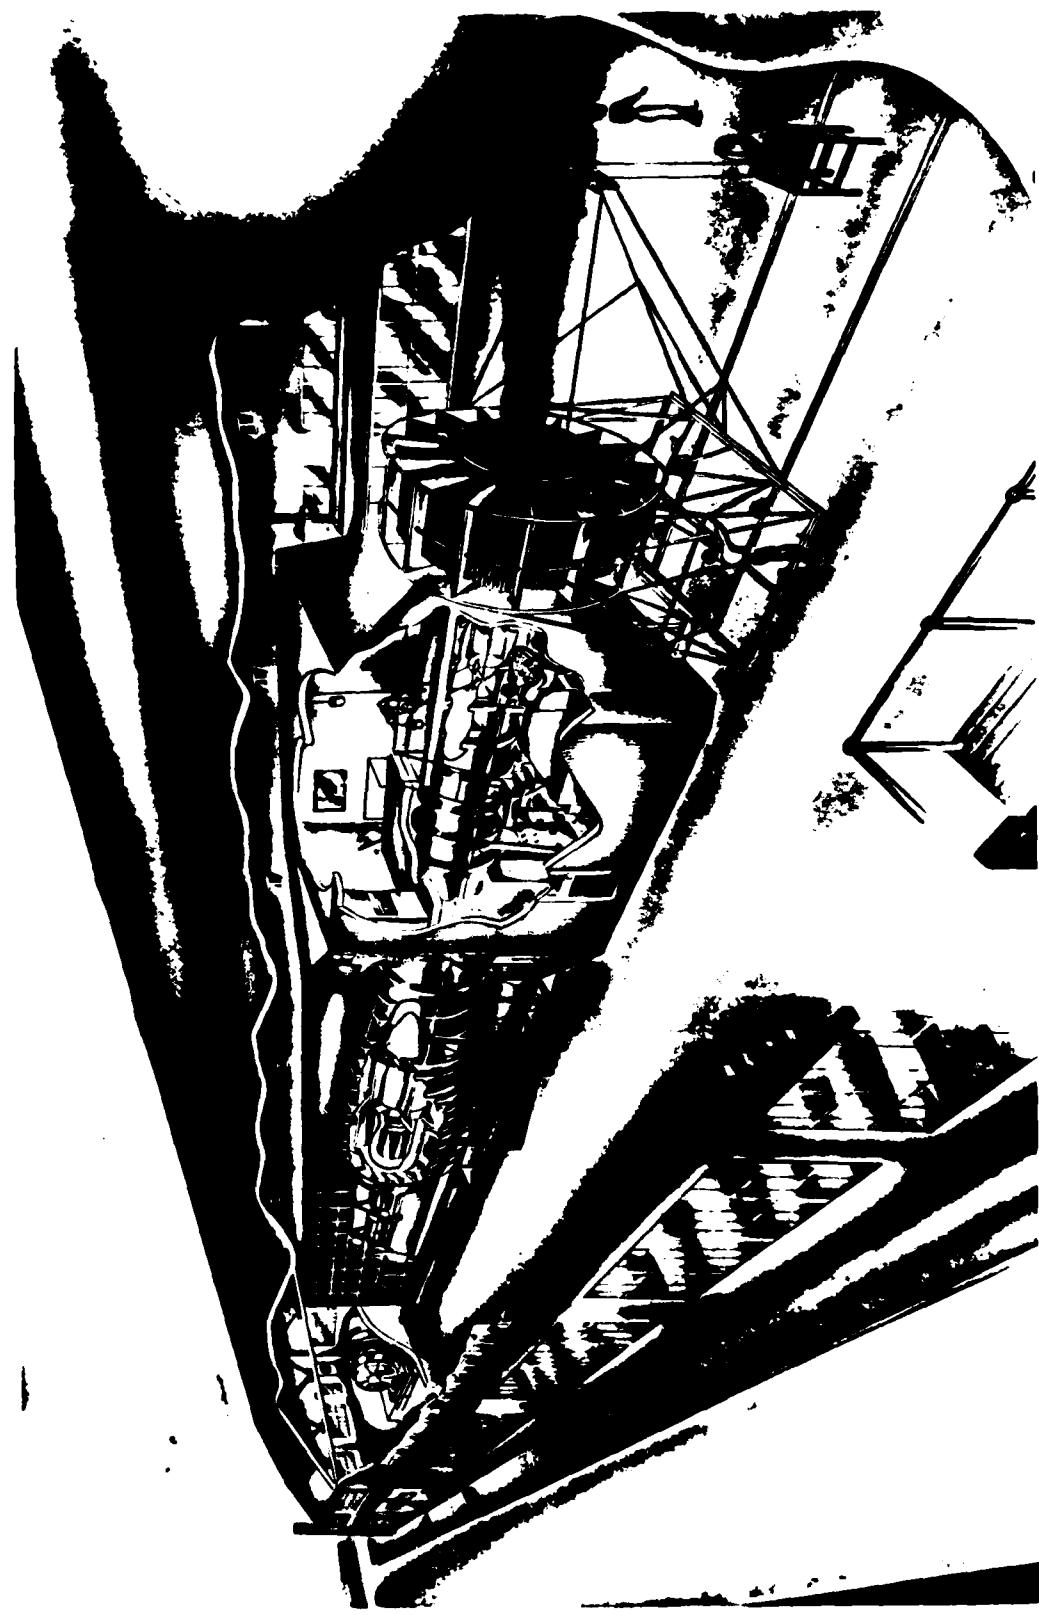

Fig. 9 AFIT Five-Foot Wind Tunnel setup.

lation was accomplished by connecting the model's attachment fittings to plates permanently connected to the appropriate tunnel wire system. These connections allowed the model to rotate freely at each connection and thereby accurately transmit the aerodynamic forces produced on the model to the wire system and then to the scales for a direct measurement. The two trunnions on the leading edge were connected to the drag and front lift wires while the attachment fitting on the rear lift bar was connected to the rear lift wire. Figures 10a and 10b show a model installed in the wind tunnel.

After installing the model, the wind tunnel instruments used to set the model at a particular angle of attack were carefully calibrated prior to taking data. The calibration used an inclinometer to measure accurately the model's angle of attack with respect to the tunnel axis.

Investigation Procedure

After calibrating an installed model, it was ready for testing. The investigation objective required that enough data be gathered to plot both the change in zero-lift angle of attack divided by flap deflection ($\Delta\alpha_{L0}/\eta$) versus flap-hinge location (E) and the change in the moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/\eta$) versus E. Data for $\Delta\alpha_{L0}/\eta$ versus E was obtained by first setting the flap at 0°, 4°, or 8°, and the taking data for angles of attack of -6°, -4°, -2°, 0°, 2°, 4°, 6°, 8°, and 10°. Data for $\Delta C_{mac}/\eta$ versus E was obtained by having the model set at 0° angle of attack with the flap

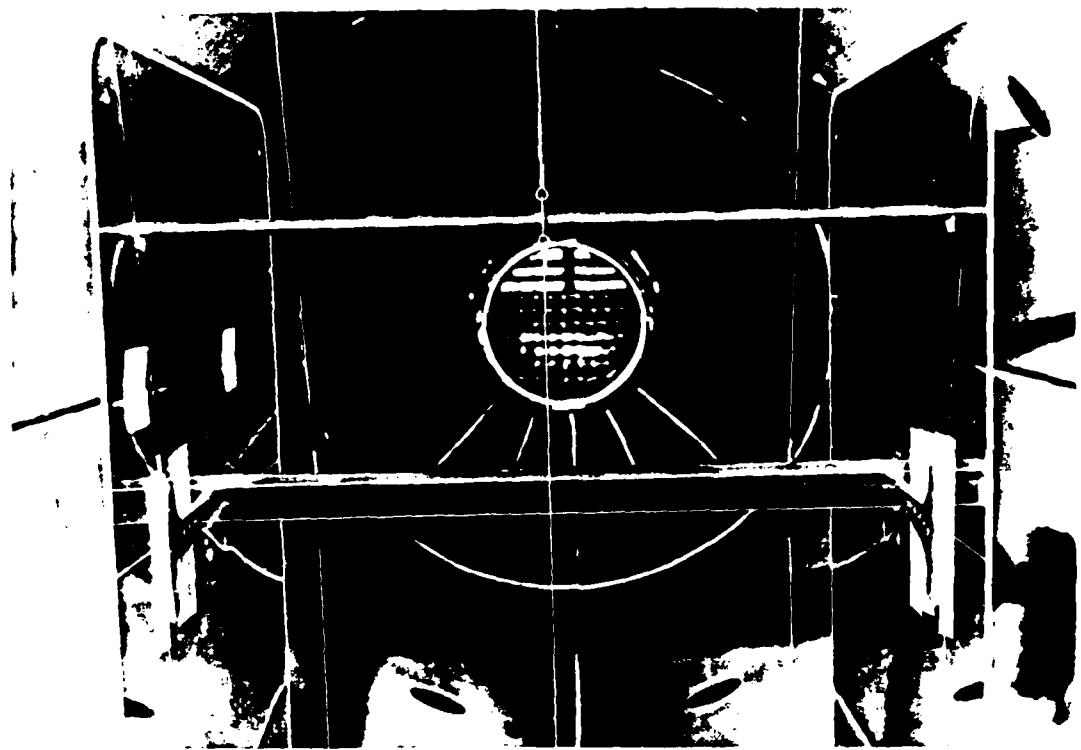

Fig. 10a Rear view of installed model.

Fig. 10b Side view of installed model.

deflected at settings from 0° to 18°. Overlap in gathering the data occurred as shown in Table I since data for $\Delta\alpha_{L0}/n$ versus E at 0° angle of attack was also used as data for $\Delta C_{mac}/n$ versus E.

A typical sequence of events used to gather data for a model is given in Table I. A typical change from one flap setting to another, an event in Table I, obtained data for $\Delta C_{mac}/n$ and $\Delta\alpha_{L0}/n$ and went as follows: The model's flap setting was changed by one degree which also required re-sealing the gaps between the front airfoil section and flap section; and taping over any uncovered holes in the side plates. Next, the model and tunnel were inspected to insure no loose objects remained in the tunnel. The tunnel doors were then secured, after which the tunnel operator aligned the model and took three before-static readings. He also ensured a current barometer and temperature reading were taken. The tunnel air was turned on and brought up to the testing dynamic pressure of three inches of water. The operator adjusted the model as the airflow increased to keep it properly aligned. With the model properly aligned and the dynamic pressure at three inches, the operator took five wind-on readings. The tunnel air was then turned off and the flow allowed to go to zero. The tunnel operator again ensured the model was aligned properly and took three after-static readings. The process for an event as listed in Table I was then complete and the tunnel could again be entered to change the model's flap setting. Data for $\Delta\alpha_{L0}/n$ also required changes

TABLE I

in angle of attack for the flap settings of 0°, 4°, and 8°. The changes in angle of attack were accomplished from outside the test section and allowed the tunnel air to remain on from one angle of attack to another. Five wind-on readings were taken for each angle of attack while three static readings were taken for each angle of attack during the before-statics and after-statics portions of the event.

Tuft studies were conducted on the .2, .4, .5, .6, and .8 E models after obtaining the force data for that individual model. These visual studies indicated the extent of separation on the airfoil's upper surface and were used later to eliminate data for those particular angles of attack and flap settings which showed separation. Appendix E gives the results of the tuft studies.

Data

The data readings for any one setting of angle of attack and flap deflection usually consisted of three before-static readings, five wind-on readings, and three after-static readings. The multiple readings helped to identify bad data and reduce scatter through averaging. Additionally, repeat readings were taken to verify the consistency and repeatability of the data. The static readings determined the loads on the model when the airflow was zero while the wind-on readings determined the loads with air flowing over the model.

Each time a reading was taken, the respective loads on all three scales (drag, rear lift, and front lift) were printed on separate paper tapes. The readings on each tape

were transferred to respective tables with line entries containing static and wind-on readings gathered for a particular angle of attack and flap setting combination. An average static value for any combination was obtained by averaging all the static readings for that combination. An average wind-on reading consisted of only averaging the five wind-on readings for a particular event. In other words, any set of five wind-on readings were averaged and treated as a separate result from any other five wind-on readings. The aerodynamic forces on the model for any particular combination of angle of attack and flap setting were found by subtracting the wind-on averages from the static averages to give drag forces, rear lift forces, and front lift forces. Appendix F contains the raw data (data attainable directly from the scale tapes) obtained during the investigation for each of the seven models.

IV Results

Data Reduction

The data in Appendix F was first reduced to obtain lift coefficient versus angle of attack graphs for each of the models. The lift coefficient (C_L) for a particular angle of attack (α), flap setting, and model was obtained by adding the forces from the raw front lift and rear lift tables and then dividing by the dynamic pressure times the wing span times the chord length (qbc). Since lift data for changing angles of attack were obtained for flap deflections of 0° , 4° , and 8° , this produced three C_L versus α plots for each model. Each plot intersected the α axis where the lift coefficient was zero, this determined the value of the zero-lift angle of attack (α_{L0}) for a specific flap deflection (n) of 0° , 4° , or 8° . Three changes in zero-lift angle of attack divided by the flap deflection ($\Delta\alpha_{L0}/n$) were then obtained by subtracting α_{L0} at $0^\circ n$ from α_{L0} at $4^\circ n$ and then dividing by 4° , α_{L0} at $4^\circ n$ from α_{L0} at $8^\circ n$ and dividing by 4° , and finally α_{L0} at $0^\circ n$ from α_{L0} at $8^\circ n$ and dividing by 8° . These values of $\Delta\alpha_{L0}/n$ were then plotted versus the value of the flap-chord ratio (E) for the model data being reduced and against the theoretical curve from Fig. 2. This gave Fig. 11 which compares experiment to theory for $\Delta\alpha_{L0}/n$ versus E .

The raw wind-tunnel data was also reduced to obtain the change of moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/n$) for each model. By

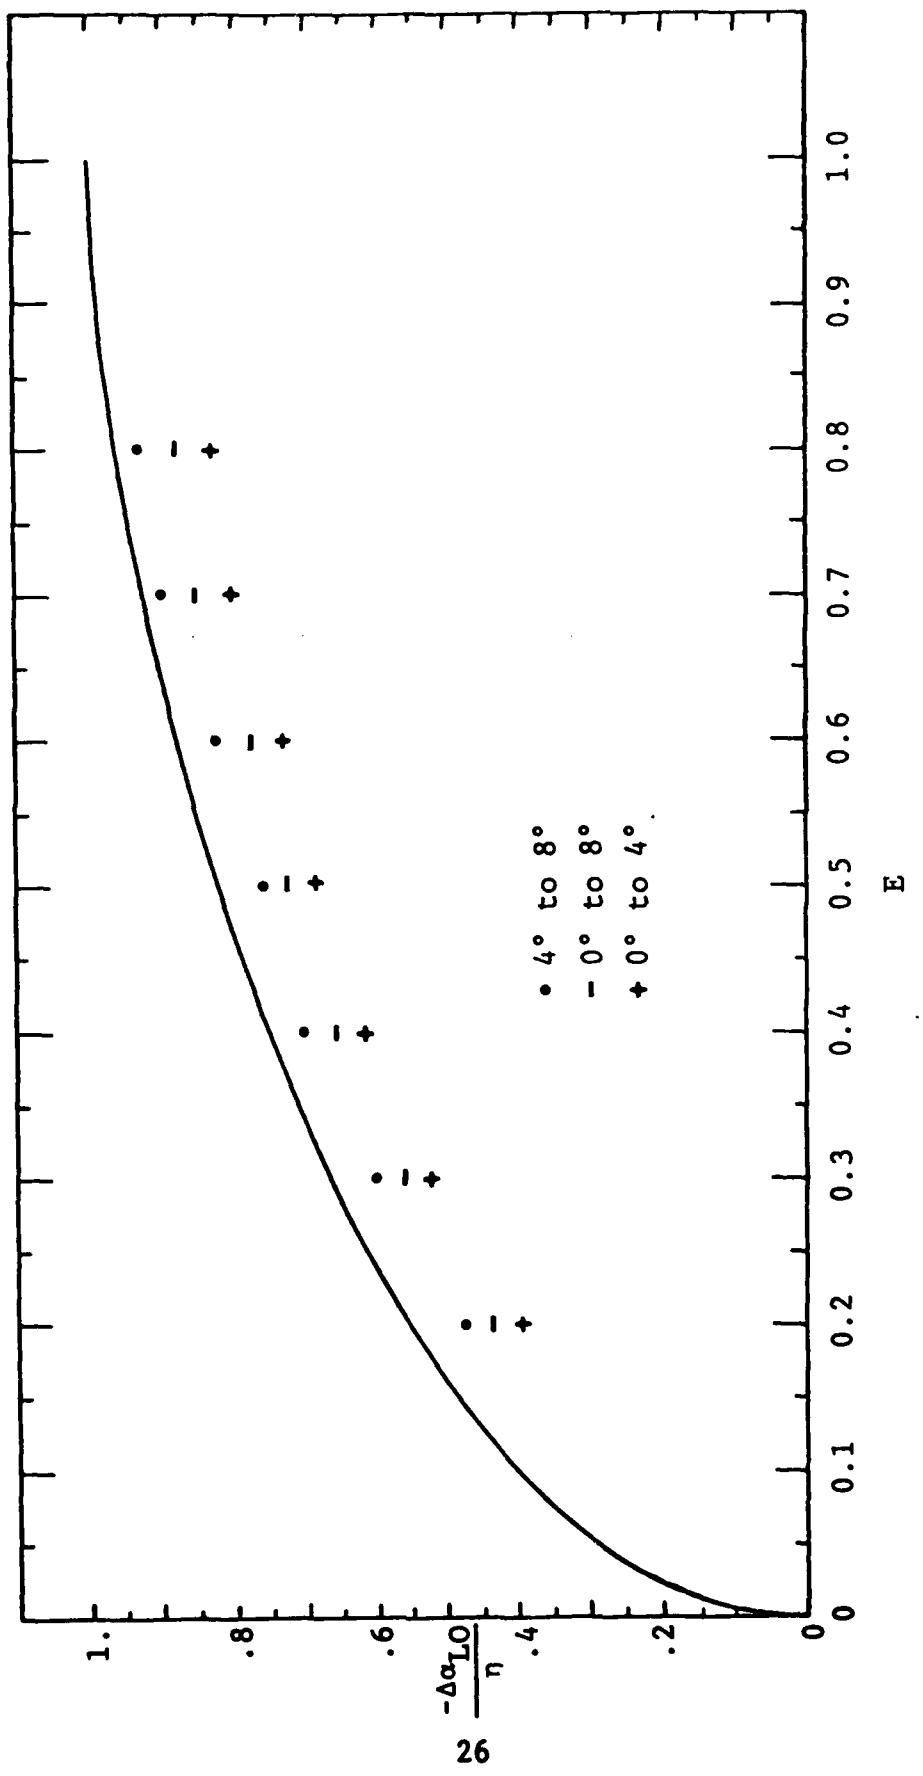

Fig. 11 Experiment versus theory for $\Delta\alpha_L/\eta$ versus E .

summing moments from the rear lift and front lift forces about an assumed aerodynamic center of .245c and then dividing by qbc^2 , the C_{mac} was obtained. This was done for data at zero degrees angle of attack and varying flap deflections to obtain a graph of C_{mac} versus η . $\Delta C_{mac}/\eta$ was then obtained by simply measuring the slope of the C_{mac} versus η line. This value was then plotted for the particular model falp-chord ratio against the theoretical curve in Fig. 4 to produce Fig. 12 which again compares experiment to theory.

Comparison of Experimental Data to Theoretical Predictions

Figure 11 shows the experimental data plotted with the theoretical curve for $\Delta\alpha_{L0}/\eta$ versus E. Here the experimental data compares favorably with the theoretical curve from both a trend and numerical standpoint. However, for the small flap deflections used, only one experimental curve was expected instead of three. This seems to imply that the data could be biased in some manner.

Figure 12 shows the experimental data plotted with the theoretical curve for $\Delta C_{mac}/\eta$ versus E. Here, the experimental data indicates the same general trend as the theoretical curve but the positive numbers for E = .6, .7, and .8 are not possible unless again the data has been biased. Since it has already been established in Section II that the theoretical curves are, for all practical purposes, the same for cambered and uncambered flapped airfoils, it is reasonable to assume that the experimental data gathered for a cambered flapped airfoil should be almost the same as the uncambered data. The

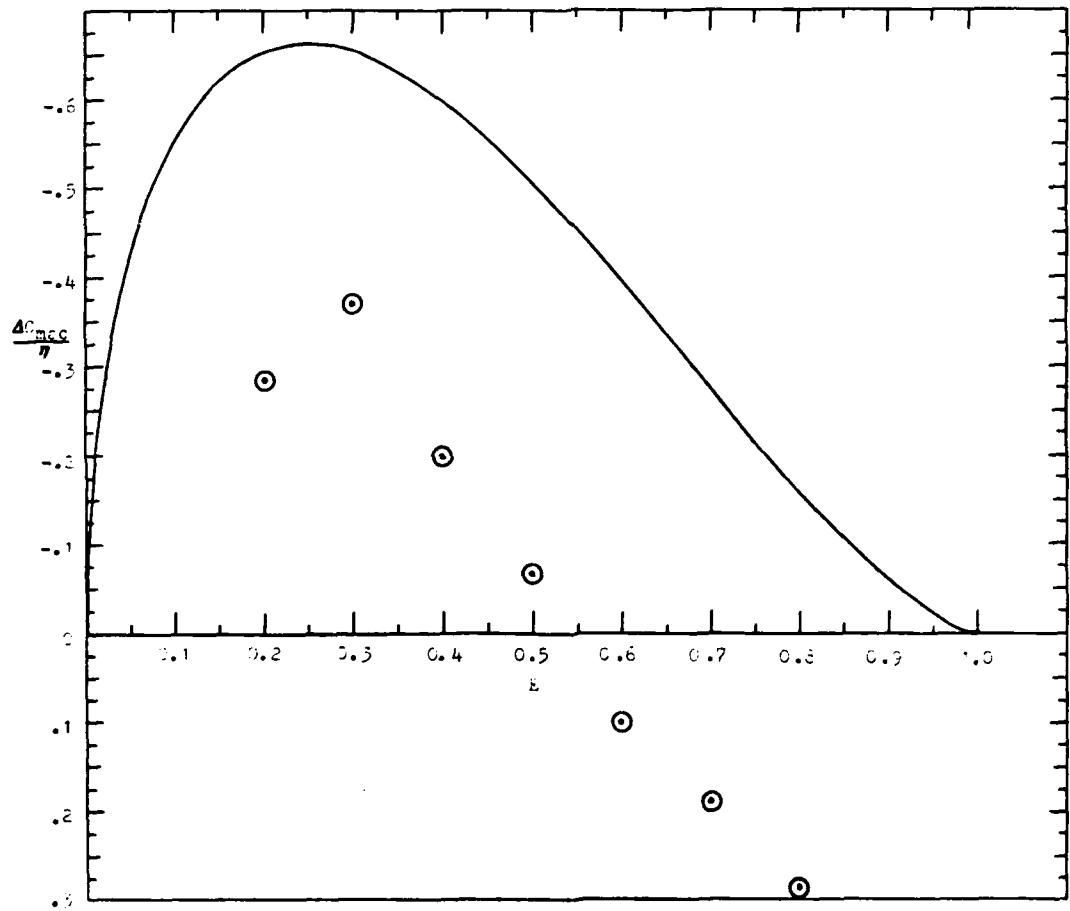

Fig. 12 Experiment versus theory for
 $\Delta C_{\text{mac}}/\eta$ versus E.

experimental data in both Figs. 11 and 12 are overall lower than the results given by Schlichting (Ref 4:65) for an uncambered airfoil with hinged flaps. This also indicates that the data could be biased in some manner.

Corrections for the experimental data were not found. Therefore, the experimental data presented only serves to confirm the general trend of the theoretical predictions.

V Conclusions and Recommendations

Conclusions

The experimental data gathered during the investigation was biased in some manner to produce results which at best can only be used to confirm the trend of the theoretical predictions of the change in the zero-lift angle of attack divided by flap deflection ($\Delta\alpha_{LO}/\eta$) versus the flap-hinge location (E) and the change in the moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/\eta$) versus E. The data can not be used to meet the thesis objective of predicting $\Delta\alpha_{LO}/\eta$ versus E and $\Delta C_{mac}/\eta$ versus E for a NACA 4412 airfoil.

While there is no direct evidence as to what was biasing the experiment, there are several indirect items which point to a major problem. That major problem would seem to be the rear lift bar. If we assume the models were reasonable reproductions of the 4412 airfoil, then, a downward force was produced to counteract the airfoil's lift. The downward force had to be occurring because from Ref 5 the zero-lift angle of attack for a 4412 airfoil is approximately 3.9° , while this investigation had a zero-lift angle of attack of approximately 2° as demonstrated from the C_L versus α graphs in Appendix H. This is a large difference which implies that something was shifting the C_L versus α graph to the right/producing a downward force. That much change could come from another lifting surface which the rear lift bar definitely was as shown by the

cross sectional view in Fig. 7. The rear lift bar was also located in a position where it could be influenced by downwash changes from changes in the amount of flap deflection. This could account for the large changes in the slope of the C_L versus α graphs as the flap was deflected. Take for example the model with $E = .8$, the slope, in units 1/radian, of the C_L versus α graph goes from 5.809 with $0^\circ\alpha$ to 5.602 with $4^\circ\alpha$, and to 5.204 with $8^\circ\alpha$. In other words, the amount of flap deflection changed the forces on the rear lift bar which in turn effected the model results. The statements in this paragraph imply that the rear lift bar was influencing/biasing the experiment. Unfortunately, no way has been found to make acceptable corrections involving the rear lift bar from the data gathered during the investigation.

Recommendations

If the investigation is accomplished again using the same basic airfoils and model, I would like to recommend some changes which may prove useful. First, eliminate the rear lift bar by modifying the airfoil to accommodate a sting for connecting the rear lift wire to the model or by replacing the rear lift bar with one of cylindrical shape. Both changes have inherent problems but the rear lift bar used in this investigation is unacceptable and must be changed or eliminated. Second, modify the side plates to make them larger and round. Although no evidence exists as to any effect the side plates had on the investigation, the plates are aligned into the free stream differently when the angle of attack is changing which could be

causing different forces on the plates themselves and therefore the model as the angle of attack changes. Third, cut down the flap deflection mechanism so that only flap deflections of 0° to 12° can be accomplished. This provides more than enough data points to plot and eliminates wasted effort since the tuft studies showed that little data is gained above 12° before separation on the upper surface occurs. Also round off the edges of the flap deflection mechanism and cut down the size of the mechanism along the attachment holes so that the mechanism disturbs the flow as little as possible. Fourth, find someway to seal the gaps on the whole airfoil besides modeling clay. The clay can never be put on the same way twice; tape or wax might be two other possibilities. Finally, the manner in which the investigation is conducted could be changed to help produce successful results. The investigation could be conducted at a higher dynamic pressure than 3 inches of water to provide a Reynolds number of the same magnitude that Abbott and Doenhoff had for their experiments with the 4412. This may involve changing the side plates to a different material than plexiglass or providing stiffeners for the plexiglass to accommodate the increase in tunnel speed. It would be very useful to find the drag and lift of any side plates through wind-tunnel testing so that they can be accurately accounted for during the investigation. When taking data, angle of attack changes could be accomplished in one degree increments and with flap deflections of 0° , 2° , 4° , 6° , and 8° . This increase in data should result in more accurate curves and

and provide a better representation of the actual situation. These recommendations are based on problems encountered during this investigation and hopefully will prove useful if the investigation is accomplished again.

Appendix A

Analytical Solution for α_{L0} and C_{mac}

Thin-airfoil theory gives $\alpha_{L0} = \frac{-1}{\pi} \int_0^{\pi} \frac{dz}{dx} (\cos \theta - 1) d\theta$ and $C_{mac} = \frac{1}{2} \int_0^{\pi} \frac{dz}{dx} (\cos 2\theta - \cos \theta) d\theta$. These equations can be analytically integrated for an NACA 4412 airfoil to give numbers for α_{L0} and C_{mac} .

The camber line of a 4 digit NACA airfoil consists of two parabolic arcs tangent at the camber line's maximum ordinate. The equations defining the camber line are

$$\frac{z}{c} = \frac{m}{p^2} \left[2p \frac{x}{c} - \left(\frac{x}{c} \right)^2 \right] \quad (18)$$

forward of maximum ordinate and

$$\frac{z}{c} = \frac{m}{(1-p)^2} \left[(1-2p) + 2p \frac{x}{c} - \left(\frac{x}{c} \right)^2 \right] \quad (19)$$

aft of the maximum ordinate where m equals the maximum ordinate of the camber line expressed as a fraction of the chord and p equals the chord wise position of the maximum ordinate in tenths of the chord. The 4 digit NACA airfoil numbering system gives the values of m and p . The first digit divided by 100 is m and the second digit divided by 10 is p . (Ref 5: 113,114)

The integral equations from Section I to be solved are

$$\alpha_{L0} = \frac{-1}{\pi} \int_0^{\pi} \frac{dz}{dx} (\cos \theta - 1) d\theta \quad (12)$$

and

$$C_{mac} = \frac{1}{2} \int_0^{\pi} \frac{dz}{dx} (\cos 2\theta - \cos \theta) d\theta \quad (13)$$

The only other piece of information needed to accomplish the integration is the function relating x and θ which is $x = .5c(1 - \cos \theta)$. Thus, finding $\frac{dz}{dx}$ from equations 18 and 19 and substituting for $\frac{dz}{dx}$ and x in equation 12

$$\alpha_{LO} = \frac{-1}{\pi} \left[\int_0^{\beta} \left[\frac{2m}{p} - \frac{2mx}{p^2 c} \right] (\cos \theta - 1) d\theta + \int_{\beta}^{\pi} \left[\frac{2mp}{(1-p)^2} - \frac{2mx}{(1-p)^2 c} \right] (\cos \theta - 1) d\theta \right] \quad (20)$$

where β is the angle corresponding to the maximum ordinate.

Using the 4412 values for m and p , and substituting for x again

$$\alpha_{LO} = \frac{-1}{\pi} \left[\int_0^{\beta} [.2 - .25(1 - \cos \theta)] (\cos \theta - 1) d\theta + \int_{\beta}^{\pi} \left[\frac{.8}{9} - \frac{1 - \cos \theta}{9} \right] (\cos \theta - 1) d\theta \right] \quad (21)$$

The angle β corresponding to m and p can be found easily by substituting in the value for x at the maximum ordinate into the equation $x = .5c(1 - \cos \theta)$. Thus, for the 4412, $.4c = .5c(1 - \cos \beta)$ which implies that $\cos \beta = .2$ and therefore $\beta = 1.3694384$ radians. By expanding the integral and putting the numerical value of β into equation 21

$$\alpha_{LO} = \frac{-1}{\pi} \left[\int_0^{1.369} [.2(\cos \theta - 1) - .25(2\cos \theta - 1 - \cos^2 \theta)] d\theta + \int_{1.369}^{\pi} \left[\frac{.8}{9} (\cos \theta - 1) - \frac{1}{9} (2 \cos \theta - 1 - \cos^2 \theta) \right] d\theta \right] \quad (22)$$

After integrating equation 22

$$\alpha_{LO} = \frac{-1}{\pi} \left[\left[.2 (\sin \theta - \theta) - .5 \sin \theta + .25\theta + .25 \left[\frac{\theta}{2} + \frac{\sin 2\theta}{4} \right] \right] \Big|_0^{1.369} + \left[\frac{.8}{9} (\sin \theta - \theta) - \frac{2}{9} \sin \theta + \frac{\theta}{9} + \frac{1}{9} \left[\frac{\theta}{2} + \frac{\sin 2\theta}{4} \right] \right] \Big|_{1.369}^{\pi} \right] \quad (23)$$

By putting in the limits for θ , we arrive at

$$\alpha_{LO} = \frac{-1}{\pi} (.227795) = -.0725094 \text{ radians} = -4.1544826 \text{ degrees}$$

Following the same steps as for α_{LO}

$$c_{mac} = \frac{1}{2} \left[\int_0^{1.369} [.2(\cos 2\theta - \cos \theta) - .25(1 - \cos \theta)(\cos 2\theta - \cos \theta)] d\theta + \int_{1.369}^{\pi} \left[\frac{.8}{9} (\cos 2\theta - \cos \theta) - \frac{1}{9} (1 - \cos \theta)(\cos 2\theta - \cos \theta) \right] d\theta \right] \quad (24)$$

$$c_{mac} = \frac{1}{2} \left[\left[.2 \left[\frac{\sin 2\theta}{2} - \sin \theta \right] - .25 \left[\frac{\sin 2\theta}{2} - \sin \theta + \frac{\theta}{2} + \frac{\sin 2\theta}{4} \right] \right. \right. \\ \left. \left. + .125 \left[\sin \theta + \frac{\sin 3\theta}{3} \right] \right] \Big|_0^{1.369} + \left[\frac{.8}{9} \left[\frac{\sin 2\theta}{2} - \sin \theta \right] \right. \\ \left. - \frac{1}{9} \left[\frac{\sin 2\theta}{2} - \sin \theta + \frac{\theta}{2} + \frac{\sin 2\theta}{4} \right] + .0555556 \left[\sin \theta + \frac{\sin 3\theta}{3} \right] \right] \Big|_{1.369}^{\pi} \right] \\ (25)$$

$$c_{mac} = \frac{1}{2} (-.2124781) = -.1062391$$

Appendix B

Computer Program

This appendix contains the listing of the computer program used to find the theoretical predictions for zero-lift angle of attack (α_{L0}), moment coefficient about the aerodynamic center (C_{mac}), change in α_{L0} divided by flap deflection ($\Delta\alpha_{L0}/\eta$) versus the flap-chord ratio (E), and $\Delta C_{mac}/\eta$ versus E as given in Section II. Comment cards in the program define the variables, parameters, and limitations. The program used numerical integration to calculate the predictions.

The program did not attempt to keep computer time to a minimum or provide a program which needed a minimal number of segments to obtain accurate results. The objective was simply to obtain accurate results as demonstrated by the comparison between the analytic solution and the program solution for α_{L0} and C_{mac} at the top of page 6. It should be pointed out that the method used in this program, the trapezoidal rule of integration, does have inherent errors and requires a relatively large number of segments to achieve accurate results. The accuracy could be improved and the number of segments needed to compute an accurate solution could be reduced by using a different numerical integration method. Since the mean camber line of the NACA 4412 airfoil is a parabolic arc, Simpson's Rule which uses parabolic arcs could be used to produce better accuracy with fewer segments when compared to the results of this program.

Appendix C

Model Geometry

The side plates were two and one-half feet square with each corner rounded to an arc with a four inch radius. The rear lift bar dimensions were 1.15 inches in chord length and .5 inches in thickness, see Fig. 7. See Abbott and Von Doenhoff (Ref 5:113,114, and 414) for cross section dimensions of the NACA 4412 airfoil.

Table II gives the airfoil measurements needed to compute C_{ℓ} s and C_{mac} s for each model.

TABLE II
Airfoil measurements

Model E	Chord length (inches)	Wing span (feet)	Distance from trunnion screw to leading edge of airfoil (inches)
.2	8.9	1.992	.3
.3	8.9	1.992	.31
.4	8.88	1.992	.31
.5	8.88	1.987	.33
.6	8.89	1.992	.3
.7	8.88	1.99	.3
.8	8.9	1.99	.3

The model's angle of attack was set by moving the rear lift wire forward or backward and increasing or decreasing the length of the rear wire from the scale to the rear lift

bar attachment fitting. The angle of balance in Fig. 13 determined the distance forward or backward the rear lift wire had to move for a specific angle of attack while the shortening or lengthening of the wire was determined during calibration. Table III gives the balance angles and model measurements, shown in Fig. 13, that determined them. Table III shows that the balance angles and model measurements varied barely at all. For that reason, the first model tested with $E = .4$ determined the angle of balance, and therefore the distances the rear lift wire moved, for the entire investigation.

TABLE III
Balance angles and associated measurements

Model E	Distances in Fig. 13 (inches)			Balance angle (degrees)
	e	f	$g=\sqrt{e^2+f^2}$	
.2	15.737	9.545	18.405	31.238
.3	15.776	9.637	18.487	31.419
.4	15.71	9.516	18.367	31.204
.5	15.726	9.577	18.413	31.341
.6	15.684	9.599	18.388	31.468
.7	15.737	9.572	18.419	31.31
.8	15.741	9.694	18.487	31.627

The distances the rear wire moved are given in Table IV. The distance and direction of movement for a specific angle of attack in Table IV was determined by calculating a new balance angle for each angle of attack. The new balance

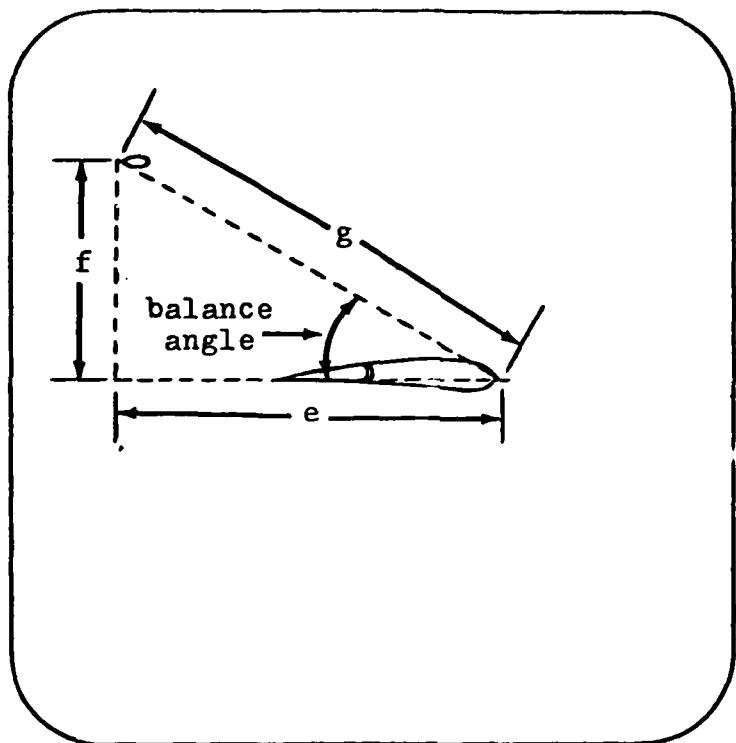

Fig. 13 Balance angle and associated measurements.

e was the horizontal distance and f was the vertical distance from the front trunnion to rear lift wire attachment fitting with $g = \sqrt{e^2 + f^2}$.

angle gave a new distance, e in Fig. 13, to the rear fitting from the front trunnion. The difference between the distance e at 0° angle of attack and e at a specific angle of attack gave the distance and direction the rear lift wire was moved. These distances were put on a bar graph and used to set the rear lift wire from the wind-tunnel operator's station during testing that required changing the angle of attack. As stated previously the distances of movement in Table IV were used for the entire investigation and came from the model with E = .4. The same distances were calculated for all the models

and for all practical purposes do not vary. For example, the model with $E = .8$ gave a maximum difference from the distances in Table IV at the angle of attack of 10° and amounted to only -.031 inches.

TABLE IV
Rear lift wire movement

Angle of attack (degrees)	Balance angle (in degrees)	Horizontal distance e (inches)	Rear lift wire movement + towards airfoil - away from airfoil (inches)
0	31.204	15.71	0
-6	37.204	14.629	1.081
-4	35.204	15.008	.703
-2	33.204	15.368	.342
2	29.204	16.033	-.323
4	27.204	16.336	-.626
6	25.204	16.619	-.909
8	23.204	16.882	-1.172
10	21.204	17.124	-1.414

Appendix D

Flap Deflection Settings

Flap deflections were accomplished by aligning one of the holes (1-7) of the brass plate/flap deflection mechanism in Fig. 6 with one of the holes in the side plate in Fig. 14. Each set of vertical holes were used with a particular model as shown in Fig. 8. Additionally, each set was drilled in a circular arc about the flap-hinge point of the particular model the set was used with. This allowed each hole of a set to be spaced at 6° intervals. The holes (1-7) of the brass plate were drilled in a circular arc about the hinge point A, see Fig. 6, of the brass plate but were separated by 5° instead of 6° . The differences in the increment between holes in the brass plate, 5° , and a set of vertical holes in the side plate, 6° , allowed flap deflections of 0° to 20° either up or down. By numbering each set of vertical holes as shown in Fig. 14 and using the numbering system in Fig. 6 for the holes in the brass plate, Table V was developed to give the flap deflection for particular combinations/alignments of holes in the brass and side plates. Take for example the flap deflection shown in Fig. 14. The set of vertical holes being used tells you that the particular model had a flap-hinge location (E) of .4. The side plate hole number used was 6 and the hole number for the brass plate was 5. For no deflection at all, both numbers must be 4. So, if the brass plate hole number 4 was aligned and set with hole number 6 of the side

plate, the deflection would be 12° downward since the side plate holes were spaced at 6° . But, since the brass plate hole was 5, that had the effect of bringing the flap back upward by 5° to give a flap deflection of 7° downward. The thinking process in the above example can be accomplished to arrive at each of the flap deflections in Table V.

$$E = .8 .7 .6 .5 .4 .3 .2$$

Fig. 14 Side view of flap deflection mechanism in operation. The number above each set of 7 vertical holes designates the model's flap-hinge location used with that set of holes. The vertical numbering system designates the side plate hole numbers.

TABLE V
Hole alignments for flap deflection

Flap setting (degrees)	Hole alignment	
	Brass plate hole # (Fig.6)	Side plate hole # (Fig.14)
0	4	4
1	5	5
2	6	6
3	7	7
4	2	3
5	3	4
6	4	5
7	5	6
8	6	7
9	1	3

17	3	6
18	4	7
-1	3	3
-2	2	2

Note: $\pm 14^\circ$ flap setting can not be achieved.

Appendix E

Tuft Studies

Tuft studies were accomplished by placing nylon strings on the upper surface of the airfoil, see Fig. 15. Table VI gives the results of the studies by indicating the combination of flap setting and angle of attack at which separation was first noticed. Figures 16 through 21 determined the data for model with $E = .8$ in Table VI. The figures were obtained by taking pictures through a window on top of the wind tunnel.

TABLE VI
Angles of separation from tuft studies

Model flap-chord ratio (E)	Angle of attack fixed at 0°	Separation angle of attack for flap fixed at		
	Separation flap angle	0°	4°	8°
.2	13°	10°	8°	8°
.4	11°	-	10°	6°
.5	12°	10°	8°	6°
.6	10°	10°	8°	6°
.8	15°	10°	8°	6°

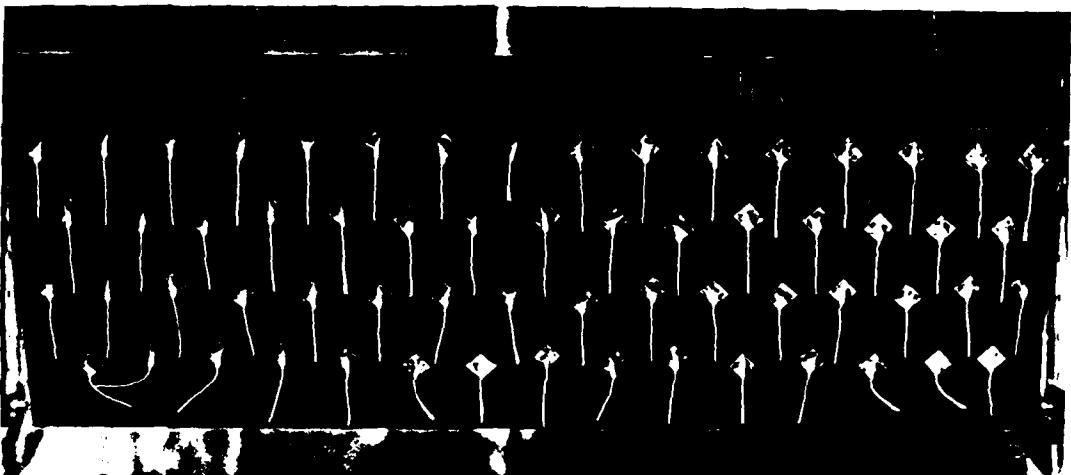

Fig. 21 0° angle of attack and 15° flap deflection.

Appendix F

Raw Tunnel Data

The following tables contain the data taken directly from the wind-tunnel tapes for all seven models. The tables for a particular model are indexed into three parts with part a containing the front lift data, part b the rear lift data, and part c the drag data. The drag tables contain the temperatures in degrees Fahrenheit and the pressures in inches of mercury that occurred during the testing of each model. Angles of attack (α) and flap deflections (η) are in degrees while the forces and wind-on/static readings are in pounds. The force column in each table was computed by subtracting the wind-on average from the static average. The forces were used as explained in Appendix G to calculate the experimental data points.

TABLE VIIa
Raw Front Lift Data for Model with $E = .2$

Appendix G

Data Reduction Calculations

This appendix explains in detail and by example how the experimental data in Appendix F was reduced to obtain the experimental points for the plots of experiment versus theory for the change in zero-lift angle of attack divided by flap deflection ($\Delta\alpha_{L0}/n$) versus flap-chord ratio (E) and the change in moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/n$) versus E, Figs. 22 thru 28 in Appendix H. The model used as the example is E = .7. The reduction process for the $\Delta\alpha_{L0}/n$ versus E experimental points will be described first.

The total lift generated by the model at a particular angle of attack and flap setting was obtained by adding the lift force from the raw front lift data to the lift force from the raw rear lift data. The lift was then divided by the dynamic pressure times the wing span times the chord length (qbc) to produce the lift coefficient, C_L . The dynamic pressure was converted from 3 inches of water to lbs/ft^2 by finding the weight of one cubic foot of water at the testing temp, dividing by 12 to give the weight of one inch of water on one square foot, and then multiplying by 3 to give the pressure of 3 inches of water in lbs/ft^2 . At this point, C_L should have been corrected for any errors induced by the wind tunnel. However, the corrections from Pope (Ref 6:305-318)

for the two dimensional wind tunnel were so small that they were considered negligible for these models. C_l was then plotted versus its angle of attack for a particular flap deflection. This process was accomplished for the three flap settings of 0° , 4° , and 8° at angles of attack -6° , -4° , -2° , 0° , 2° , 4° , 6° , 8° , and 10° . This gave three plots for C_l versus α for a model with a particular E . Each plot had an angle of zero-lift and by subtracting them appropriately the changes in the angle of zero-lift ($\Delta\alpha_{L0}$) were found. Dividing the $\Delta\alpha_{L0}$ s by the appropriate change in flap deflection then gave three $\Delta\alpha_{L0}/n$ experimental points for a model with a particular E . Table XIV gives the numerical values for L , q_{bc} , and C_l for the model with $E = .7$. Figures 22a through 28b give the values for α_{L0} for all seven models.

$\Delta C_{mac}/n$ versus E experimental points were obtained in a manner similar to $\Delta\alpha_{L0}/n$ versus E points. The calculations about to be presented were initially done with an assumed aerodynamic center of $.25c$. This resulted in a positive result for $\Delta C_{mac}/n$ for $E = .7$ and was the first indication that the data was biased in some manner. Calculations for the aerodynamic center from the data at 0° flap deflection gave an x_{ac} location of approximately 4 inches which was not possible for the 9 inch 4412 airfoil. In fact, for the low Reynolds number of the airfoil in this experiment, it was more likely that the aerodynamic center was in front of the quarter chord. Since no reliable data for the Reynolds number of approx 5×10^5 could be found, an assumed location of $.245c$ was

TABLE XIV
Calculations for Model with $E = .7$

made from trends of the aerodynamic center location in Abbott and Doenhoff (Ref 5:489). The calculations were then repeated with .245c. The forces for the moment were the rear lift and front lift with the front lift producing a positive moment and the rear lift producing a negative moment when the rear lift was positive. The moment arm for the front lift was found by taking .245c of the chord length plus the distance from the trunnion screw to the model, 2.476 inches for $E = .7$. The rear moment arm was found by subtracting the front lift moment arm from the horizontal distance e as given in Table III, thus the rear lift moment arm for the $E = .7$ model was 13.261 inches. After finding the moment for a particular flap setting at 0° angle of attack, it was then divided by qbc^2 to give C_{mac} . Table XIV gives the calculations for C_{mac} with $E = .7$. This value of C_{mac} was then plotted against the value of the flap deflection it was computed for. By doing this for flap deflections from 0° to 13° at an angle of attack of 0° , the C_{mac} versus η figures in Appendix H were obtained. The experimental $\Delta C_{mac}/\eta$ points for a particular E was then found by measuring the slope of the corresponding C_{mac} versus η figure.

Appendix H

Experimental Data Plots

This Appendix contains the experimental plots of the lift coefficient versus angle of attack and the moment coefficient about the aerodynamic center versus flap deflection for all seven models. The plots were used to determine the change in zero-lift angle of attack divided by flap deflection versus flap-chord ratio and the change in the moment coefficient about the aerodynamic center divided by flap deflection versus flap-chord ratio. The points for the plots came from reducing the experimental data in Appendix F with the method of reduction described in Appendix G.

VITA

Howard J. Price, Jr. was born on 25 Jan 1949 in Benham, Kentucky. He graduated from high school in Richmond, Indiana in 1966 and then attended Purdue University to receive the degree of Bachelor of Science in Aeronautical and Astronautical Engineering in Jun 1970. He received his commission in the USAF through the Officer Training School program in Aug 1971. He completed Undergraduate Pilot Training to earn the aeronautical rating of pilot in Sep 1972. His first flying assignment was to Fairchild AFB, Washington to fly B-52s with the 325th Bombardment Squadron from Sept 1972 to Oct 1976. He then flew T-37s with the 35th Flying Training Squadron at Reese AFB, Texas until entering the School of Engineering at the Air Force Institute of Technology in Jun 1981.

20. ABSTRACT (Continue on reverse side if necessary and identify by block number) This investigation compared thin-airfoil theory predictions of change in zero-lift angle of attack divided by flap deflection ($\Delta\alpha_{L0}/n$) versus flap-hinge location (E) and change in moment coefficient about the aerodynamic center divided by flap deflection ($\Delta C_{mac}/n$) versus E to wind tunnel studies of the same effect for a cambered airfoil. This comparison for cambered airfoils has not been previously reported. The NACA 4412 air-

foil was chosen for this study. Results of this study show that thin-airfoil theory does predict the trend of the data. The $\Delta\alpha_{LO}/n$ versus E prediction favorably matched the data. The $\Delta C_{mac}/n$ versus E data differed from the predictions in a similar way to that reported for uncambered airfoils; however, the data in this investigation showed less favorable agreement to thin-airfoil theory than the previously reported results. This difference might be explained in part by the experimental setup used in this study.
